Photocatalytic

## ABSTRACT

Cu<sub>2</sub>O nanoparticles (NPs) were directly formed on g-C<sub>3</sub>N<sub>4</sub> via a one-pot in-situ reduction method. The physical and photophysical properties of these Cu<sub>2</sub>O NPs modified g-C<sub>3</sub>N<sub>4</sub> photocatalysts were characterized to investigate the effects of Cu<sub>2</sub>O NPs on the photocatalytic activities of g-C<sub>3</sub>N<sub>4</sub>. Close contact was formed between Cu<sub>2</sub>O and g-C<sub>3</sub>N<sub>4</sub> and the Cu<sub>2</sub>O NPs were well dispersed on g-C<sub>3</sub>N<sub>4</sub>. The visible light photocatalytic hydrogen production activity over g-C<sub>3</sub>N<sub>4</sub> was enhanced by more than 70% with Cu<sub>2</sub>O NPs modification. It is revealed that the efficient visible light absorption and Type II band alignment induced charge separation by Cu<sub>2</sub>O NPs modification should be the key factors for improved photocatalytic performance.

## 1. Introduction

Photocatalytic water splitting to produce hydrogen has attracted great research interest due to the global energy crisis and environmental pollution since its first demonstration by Fujishima and Honda [1]. During the past few decades, many photocatalysts have been developed, such as TiO<sub>2</sub>, [2] CdS [3], etc. However, various drawbacks, such as poor absorption ability (e.g. TiO<sub>2</sub>) [2], fast recombination rate of photogenerated electron–hole pairs, and highly toxic for human health and harmful to the environment (e.g. CdS) [3] greatly limit the photocatalytic efficiency and practical application for solar hydrogen conversion. To address these limitations, novel photocatalytic materials of efficient visible light absorption and charge separation must be developed for practical application of this state-of-the-art technique for solar fuel production.

Recently, Wang et al. [4,5] reported a novel metal-free polymer n-type semiconductor, layered C<sub>3</sub>N<sub>4</sub> with a graphitic structure (g-C<sub>3</sub>N<sub>4</sub>), showing good visible light absorption property ( $E_g = 2.7$  eV) and photocatalytic stability for hydrogen production. Compared

with the most studied materials (TiO<sub>2</sub>, CdS, etc.), g-C<sub>3</sub>N<sub>4</sub> combines the advantages of low cost, nontoxicity and visible light activity, and in this regard, it should be a good candidate for photocatalytic solar conversion. However, the photocatalytic efficiency of pure g-C<sub>3</sub>N<sub>4</sub> was relatively low, mainly due to the fast recombination of photogenerated electron–hole pairs. By far, two approaches have been considered effective to increase the separation efficiency of photogenerated electron–hole pairs for g-C<sub>3</sub>N<sub>4</sub>. One is to load cocatalysts, such as Au, Pt and Ag, on the surface of catalysts [6–8]. For example, Maeda et al. found that Pt loading could greatly improve the visible light photocatalytic hydrogen production performance for g-C<sub>3</sub>N<sub>4</sub> [6], and they further loaded Au, Pt, Pd on g-C<sub>3</sub>N<sub>4</sub> and found that compared with Pt loading alone, the photocatalytic hydrogen production ability was enhanced by more than 5 times with Au, Pt coloaded [7].

The other way is to form semiconductor heterojunctions with properly aligned band structure [9,10]. Coupling with quantum dots (QDs) of narrow band gap semiconductors has been proven to be effective to improve photoactivity of g-C<sub>3</sub>N<sub>4</sub> in the visible spectrum. Ge et al. [11] reported a novel CdS QDs modified g-C<sub>3</sub>N<sub>4</sub> photocatalyst with efficient separation of the photogenerated charge carriers and thus enhanced visible light photocatalytic hydrogen production activity. Different QDs, such as CdSe [12], and Cu<sub>2</sub>O [13,14] have been coupled with other photocatalysts for better activity. Tennakone et al. [13] developed Cu<sub>2</sub>O QDs modified TiO<sub>2</sub> nanoparticles for enhanced photocatalytic activity for water photoreduction by promoting inter-particle charge transfer to suppress charge carrier recombination. Lin et al. [14] reported

Fig. 1. Schematic illustration of the fabrication of  $\text{Cu}_2\text{O}$  NPs/ $\text{g-C}_3\text{N}_4$  composite photocatalysts.

$\text{Cu}_2\text{O}/\text{TiO}_2$  p–n heterojunction composed of  $\text{Cu}_2\text{O}$  nanoparticles deposited on  $\text{TiO}_2$  and the visible light photocatalytic for degrading RhB was significantly enhanced due to broadened absorption in the visible light region and improved separation of photogenerated electrons and holes. However, nowadays, in most studies on  $\text{Cu}_2\text{O}$  modification, cumbersome two-step method was used for sample preparation and the  $\text{Cu}_2\text{O}$  particles were easy to be oxidized [15] for exposure to air during the synthesis process. To our best knowledge, there is still rare report on nano-sized  $\text{Cu}_2\text{O}$  particles modified  $\text{g-C}_3\text{N}_4$  photocatalyst prepared by a facile one-pot method for improved hydrogen production activity under visible light.

In the present study, we successfully prepared a series of  $\text{Cu}_2\text{O}$  NPs modified  $\text{g-C}_3\text{N}_4$  photocatalysts via a one-pot in-situ reduction method. The effects of  $\text{Cu}_2\text{O}$  NPs on the visible optical absorption and charge carrier separation, and hence the photocatalytic activities of  $\text{g-C}_3\text{N}_4$  were discussed in detail.

## 2. Experimental

### 2.1. Synthesis procedure

All chemicals in the present study are of analytical grade and used as received without further purification.  $\text{Cu}_2\text{O}$  NPs modified  $\text{g-C}_3\text{N}_4$  photocatalysts were prepared as illustrated in Fig. 1. Typically, 5.0 g melamine and desired volume of  $0.0760\text{ g/mL Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$  aqueous solution (typically, 1.0 mL of  $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$  aqueous solution resulting in 1.0 wt% of Cu in the as-prepared  $\text{Cu}_2\text{O}/\text{g-C}_3\text{N}_4$  photocatalyst) were added into 200 mL distilled water. The obtained solution was heated at  $90^\circ\text{C}$  for 1 h under stirring, then the temperature was raised to  $100^\circ\text{C}$  for complete water evaporation. The resulting mixture was put into an alumina crucible with a cover, and heated to  $520^\circ\text{C}$  with ramping rate of  $20^\circ\text{C}/\text{min}$  and kept at that temperature for another 4 h. This process was conducted with  $30\text{ mL}/\text{min}$   $\text{N}_2$  flow at atmospheric pressure.  $\text{g-C}_3\text{N}_4$  modified with different amounts of  $\text{Cu}_2\text{O}$  NPs is denoted as  $\text{Cu}(X\text{ wt\%})\text{-g-C}_3\text{N}_4$ , where X, ranging from 0 to 1.0, is used to note the Cu content in the as-prepared  $\text{Cu}_2\text{O}/\text{g-C}_3\text{N}_4$  photocatalyst.

Pure  $\text{g-C}_3\text{N}_4$  was prepared by the same process without adding  $\text{Cu}(\text{NO}_3)_2$ . Pure  $\text{Cu}_2\text{O}$  powders were obtained by completely decomposing  $\text{g-C}_3\text{N}_4$  in  $\text{Cu}(1.0\text{ wt\%})\text{-g-C}_3\text{N}_4$  under  $800^\circ\text{C}$  for 2 h at  $\text{N}_2$  atmosphere.  $\text{Cu}_2\text{O}/\text{g-C}_3\text{N}_4\text{-M}$  composite as reference was prepared by mechanical mixing of pure  $\text{Cu}_2\text{O}$  and pure  $\text{g-C}_3\text{N}_4$ .

### 2.2. Characterization

The transmission electron microscopy (TEM) images were obtained from a FEI Tecnai G2 F30 transmission electron microscope at an accelerating voltage of 300 kV. The X-ray diffraction (XRD) patterns were obtained from a PANalytical X'pert MPD Pro diffractometer operated at 40 kV and 40 mA using Ni-filtered  $\text{Cu K}\alpha$  irradiation (Wavelength  $1.5406\text{ \AA}$ ). UV–vis absorption spectra (UV–vis) were measured on a HITACHI U4100 instrument equipped

with labsphere diffuse reflectance accessory. The analysis of photoluminescence spectra (PL) was carried out at room temperature on a PTI QM-4 fluorescence spectrophotometer. X-ray photoelectron spectroscopy (XPS) data were obtained on a Kratos Axis-Ultra DLD instrument with a monochromatized  $\text{Al K}\alpha$  line source (150 W). All binding energies were referenced to the C 1s peak at  $284.8\text{ eV}$ .

### 2.3. Photocatalytic activity evaluation

Photocatalytic hydrogen evolution was performed in a gas-closed circulation system with an approximate 230 mL top window Pyrex cell as the photoreactor. A 300 W Xe lamp was used as the light source, and the UV part of the light was removed by a cutoff filter ( $\lambda > 420\text{ nm}$ ). Hydrogen evolved was analyzed on a thermal conductivity detector (TCD) gas chromatograph (NaX zeolite column,  $\text{N}_2$  as a carrier gas) every 60 min. In a typical experiment, the photocatalyst powder (0.1 g) was dispersed in 180 mL of 10 vol% triethanolamine (TEOA) aqueous solution under stirring. Pt (3 wt%) was photodeposited in situ on the photocatalysts from the precursor of  $\text{H}_2\text{PtCl}_6 \cdot 6\text{H}_2\text{O}$ . Nitrogen was purged through the cell for 15 min before photocatalytic reaction to remove oxygen. The temperature for all the photocatalytic reactions was kept at  $35 \pm 0.5^\circ\text{C}$  by thermostatic waterbath.

## 3. Results and discussion

### 3.1. Structure and morphology

The TEM images of the as-prepared  $\text{Cu}(X=0, 0.05, 0.5, 1.0\text{ wt\%})\text{-g-C}_3\text{N}_4$  photocatalysts are shown in Fig. 2. Fig. 2A is the TEM image of the pure  $\text{g-C}_3\text{N}_4$  photocatalyst, showing a layered structure, which offers substrate for loading of  $\text{Cu}_2\text{O}$  NPs. For the modified samples (Fig. 2B–E),  $\text{Cu}_2\text{O}$  NPs are well dispersed on  $\text{g-C}_3\text{N}_4$ . The fringes spacing measured to be  $2.46\text{ \AA}$  and  $2.13\text{ \AA}$  were corresponded to (2 1 1) and (2 0 0) lattice plane of cuprite  $\text{Cu}_2\text{O}$  (JCPDS 005-0667), respectively. As demonstrated in Fig. 2B, for the  $\text{Cu}(0.05\text{ wt\%})\text{-g-C}_3\text{N}_4$  photocatalyst,  $\text{Cu}_2\text{O}$  NPs were dispersed evenly on  $\text{g-C}_3\text{N}_4$  with a narrow size range of 3–7 nm. While X increasing to more than 0.5, larger particles appeared for  $\text{Cu}(0.5\text{ wt\%})\text{-g-C}_3\text{N}_4$  and  $\text{Cu}(1.0\text{ wt\%})\text{-g-C}_3\text{N}_4$  sample (Fig. 2C and D). The particle size distribution (Fig. 2F) was recorded by measuring more than 60 nanoparticles from TEM images for  $\text{Cu}(0.05\text{ wt\%})\text{-g-C}_3\text{N}_4$  and  $\text{Cu}(0.5\text{ wt\%})\text{-g-C}_3\text{N}_4$ . The diameters of  $\text{Cu}_2\text{O}$  NPs in  $\text{Cu}(0.05\text{ wt\%})\text{-g-C}_3\text{N}_4$  are centered at 4 nm. For  $\text{Cu}(0.5\text{ wt\%})\text{-g-C}_3\text{N}_4$ , the size distribution of  $\text{Cu}_2\text{O}$  NPs turns to be wider, and larger particles with diameter  $>10\text{ nm}$  or small particles with diameter  $<3\text{ nm}$  can be also found. Further increasing the amount of  $\text{Cu}(\text{NO}_3)_2$  precursor gives rise to more nanoparticles with larger size up to  $\sim 18\text{ nm}$ , as observed for  $\text{Cu}(1.0\text{ wt\%})\text{-g-C}_3\text{N}_4$  (Fig. 2E).

The XRD patterns of the  $\text{Cu}(X\text{ wt\%})\text{-g-C}_3\text{N}_4$  samples are presented in Fig. 3 to investigate the structure of  $\text{g-C}_3\text{N}_4$  after modifying with  $\text{Cu}_2\text{O}$  NPs. All the samples show quite similar profiles and all the diffraction peaks can be attributed to the

**Fig. 2.** TEM images of Cu(X wt%)-g-C<sub>3</sub>N<sub>4</sub> photocatalysts: (A) X=0; (B) X=0.05; (C and D) X=0.5; (E) X=1.0; (F) the particle size distribution for Cu(X=0.05, 0.5 wt%)-g-C<sub>3</sub>N<sub>4</sub>.

graphitic phase with tri-s-triazine unit in its structure [4,16]. The unchanged peak position and shape indicates that the g-C<sub>3</sub>N<sub>4</sub> nanolayer structure does not change with Cu<sub>2</sub>O modification. No Cu<sub>2</sub>O peaks were detected from the XRD patterns, mainly because the nanoparticles in those samples are well dispersed at several nanometer scale (as seen in Fig. 1) and the Cu<sub>2</sub>O contents are quite low [17,18].

### 3.2. Chemical state of Cu

To confirm the chemical state of Cu in these photocatalysts, Cu 2p XPS spectra of Cu(X wt%)-g-C<sub>3</sub>N<sub>4</sub> were analyzed, as shown in Fig. 4. The peaks at 932.4 eV and 952.1 eV are attributed to Cu<sup>2+</sup> ions according to the previous reports [15,19,20]. The Cu 2p<sub>3/2</sub> level shifted a little toward lower binding energy compared to

**Fig. 3.** X-ray diffraction patterns of Cu(X wt%)-g-C<sub>3</sub>N<sub>4</sub> photocatalysts with various X: (a) X = 1.0; (b) X = 0.7; (c) X = 0.5; (d) X = 0.2; (e) X = 0.1; (f) X = 0.05; (g) X = 0.02; (h) X = 0.

**Fig. 4.** Cu 2p XPS spectra of the Cu(X wt%)-g-C<sub>3</sub>N<sub>4</sub> photocatalysts with various X: (a) X = 1.0; (b) X = 0.7; (c) X = 0.5; (d) X = 0.2; (e) X = 0.1; (f) X = 0.05; (g) X = 0.02.

that of bulk Cu<sub>2</sub>O (932.6 eV) [20], indicating that the formed Cu<sub>2</sub>O species on g-C<sub>3</sub>N<sub>4</sub> existed as nanocrystallines or quantum dots [15]. No satellite peaks around 945.0 eV, characteristic of the Cu<sup>2+</sup> ions [21–23], were detected. The increasing intensity of Cu 2p peaks should be due to the increased content of Cu<sub>2</sub>O. As confirmed by XPS quantitative analysis, the amounts of Cu for the Cu(X = 0.1, 0.2, 0.5, 0.7, 1.0 wt%)-g-C<sub>3</sub>N<sub>4</sub> samples were calculated to be 0.09 wt%, 0.22 wt%, 0.47 wt%, 0.66 wt% and 0.94 wt%, respectively, which are very close to the value of initial Cu content. The XPS spectra of Cu 2p were undetectable when Cu content was smaller than 0.1 wt%, possibly due to the detection limit of XPS instrument.

### 3.3. Optical properties

Fig. 5 shows the UV–vis diffuse reflectance spectra of the as-prepared photocatalysts. The absorption edge of pure g-C<sub>3</sub>N<sub>4</sub>

**Fig. 5.** UV–vis diffuse reflectance spectra of pure g-C<sub>3</sub>N<sub>4</sub>, pure Cu<sub>2</sub>O and Cu(X wt%)-g-C<sub>3</sub>N<sub>4</sub> photocatalysts with various X: (a) X = 0.02; (b) X = 0.05; (c) X = 0.1; (d) X = 0.2; (e) X = 0.5; (f) X = 0.7; (g) X = 1.0.

photocatalysts was about 460 nm, with band gap ( $E_g$ ) calculated to be 2.70 eV by Kubelka–Munk method [24]. The absorption edge monotonously red-shifted from 460 nm for g-C<sub>3</sub>N<sub>4</sub> to 600 nm for Cu(1.0 wt%)-g-C<sub>3</sub>N<sub>4</sub> with increasing Cu<sub>2</sub>O loading amounts. The broadening of light absorption may be attributed to the loaded Cu<sub>2</sub>O known as a p-type semiconductor oxide with  $E_g$  of 2.0–2.4 eV, depending on the nanoparticle size [25,26]. As shown in Fig. 5, the light absorption edge of pure Cu<sub>2</sub>O with particle size of 30 nm (Fig. S1–S2) is 630 nm, corresponds to a band gap of 1.97 eV, which is in accord with the reported value [25,26]. It has also been reported that for Cu<sub>2</sub>O NPs with size of about 2–3 nm, the band gap might increase to 2.40 eV due to quantum size effect [25,26].

Photoluminescence (PL) spectroscopy has been widely used to examine the charge transfer, migration and separation in photocatalysts [27]. Fig. 6 shows the PL spectra for pure g-C<sub>3</sub>N<sub>4</sub> as well as Cu(X wt%)-g-C<sub>3</sub>N<sub>4</sub>. All the photocatalysts exhibited a broad emission peak centered at around 460 nm, corresponding to the band gap of g-C<sub>3</sub>N<sub>4</sub>, and a tail extending to 650 nm. The emission could be attributed to the band–band PL phenomenon of the photoinduced charge carriers for g-C<sub>3</sub>N<sub>4</sub> [5,9]. The PL

**Fig. 6.** Photoluminescence spectra of Cu(X wt%)-g-C<sub>3</sub>N<sub>4</sub> photocatalysts.

**Fig. 7.** VB XPS spectra for  $\text{Cu}_2\text{O}$  and  $\text{g-C}_3\text{N}_4$ . The inset is the energy band alignment of  $\text{Cu}_2\text{O/g-C}_3\text{N}_4$  heterojunction. (solid lines: band position for pure  $\text{Cu}_2\text{O}$  and  $\text{g-C}_3\text{N}_4$ ; dotted lines: estimated band position for  $\text{Cu}_2\text{O}$  nanoparticles).

emission intensity exhibits the highest value for the pure  $\text{g-C}_3\text{N}_4$  and decreases monotonously with increasing  $\text{Cu}_2\text{O}$  contents. This indicates that the recombination of photogenerated charge carriers is inhibited in the  $\text{Cu(X wt\%)-g-C}_3\text{N}_4$  photocatalysts. The charge separation in composite photocatalysts is usually attributed to the charge transfer at the interfaces, with driving force originated from the matching band potentials of the two components (e.g. type II band alignment) [28].

### 3.4. Band alignment

In the present work, the valence band maximum (VBM) edge potentials of  $\text{Cu}_2\text{O}$  and  $\text{g-C}_3\text{N}_4$  was measured by the valence band X-ray photoelectron spectroscopy (VB XPS) to demonstrate the band alignment occurred for the  $\text{Cu(X wt\%)-g-C}_3\text{N}_4$  photocatalysts. As shown in Fig. 7, the VBM energy levels of  $\text{Cu}_2\text{O}$  and  $\text{g-C}_3\text{N}_4$  were determined to be about 0.55 eV and 2.38 eV, respectively. The valence band offset (VBO,  $\Delta E_{\text{vb}}$ ) and the conduction band offset (CBO,  $\Delta E_{\text{cb}}$ ) are described by the following formula, [29,30] which is considered accurate in determining the band offset of heterojunction structure:

$$\Delta E_{\text{vb}}(\text{C}_3\text{N}_4/\text{Cu}_2\text{O}) = (E_{\text{N}1\text{s}, \text{C}_3\text{N}_4} - E_{\text{VBM}, \text{C}_3\text{N}_4}) - (E_{\text{Cu } 2\text{p}_{3/2}, \text{Cu}_2\text{O}} - E_{\text{VBM}, \text{Cu}_2\text{O}}) \quad (1)$$

$$+ (E_{\text{Cu } 2\text{p}_{3/2}, \text{interface}} - E_{\text{N } 1\text{s}, \text{interface}})$$

$$\Delta E_{\text{cb}} \left( \frac{\text{C}_3\text{N}_4}{\text{Cu}_2\text{O}} \right) = (E_{\text{g}, \text{C}_3\text{N}_4} - E_{\text{g}, \text{Cu}_2\text{O}}) - \Delta E_{\text{vb}} \left( \frac{\text{C}_3\text{N}_4}{\text{Cu}_2\text{O}} \right) \quad (2)$$

where  $(E_{\text{Cu } 2\text{p}_{3/2}, \text{interface}} - E_{\text{N } 1\text{s}, \text{interface}})$  is the energy difference between  $\text{Cu } 2\text{p}_{3/2}$  and  $\text{N } 1\text{s}$  core levels (Fig. S3), which measured in the  $\text{Cu}_2\text{O/g-C}_3\text{N}_4$  heterojunction,  $(E_{\text{N } 1\text{s}, \text{C}_3\text{N}_4} - E_{\text{VBM}, \text{C}_3\text{N}_4})$  and  $(E_{\text{Cu } 2\text{p}_{3/2}, \text{Cu}_2\text{O}} - E_{\text{VBM}, \text{Cu}_2\text{O}})$  are the  $\text{g-C}_3\text{N}_4$  and  $\text{Cu}_2\text{O}$  constants, which are obtained from each pure component. Note that the  $E_{\text{g}}$  and VBM position were measured from pure  $\text{Cu}_2\text{O}$  made by decomposing  $\text{g-C}_3\text{N}_4$  in  $\text{Cu}_2\text{O/g-C}_3\text{N}_4$  to estimate the real  $E_{\text{g}}$  and VBM values of the loaded  $\text{Cu}_2\text{O}$  NPs in the as-prepared  $\text{g-C}_3\text{N}_4/\text{Cu}_2\text{O}$  composite photocatalysts must be larger (dotted line in Fig. 7), as previously reported that the VB and CB position should oppositely separate due to the quantum size effect [14]. Based on the

**Fig. 8.** Photocatalytic  $\text{H}_2$  production under visible-light irradiation over  $\text{Cu(X wt\%)-g-C}_3\text{N}_4$  photocatalysts: (a)  $X=0$ ; (b)  $X=0.02$ ; (c)  $X=0.05$ ; (d)  $X=0.1$ ; (e)  $X=0.2$ ; (f)  $X=0.5$ ; (g)  $X=0.7$ ; (h)  $X=1.0$ ; a-mix:  $\text{Cu}_2\text{O/g-C}_3\text{N}_4$ -M, mechanical mixture of  $\text{Cu}_2\text{O}$  and  $\text{g-C}_3\text{N}_4$  with  $\text{Cu}$  content of 0.05 wt%.

above deduction, as illustrated in Fig. 7,  $\text{Cu}_2\text{O}$  displays a CB energy level 1.11 eV higher than  $\text{g-C}_3\text{N}_4$ , indicating that the photoelectrons can transfer from  $\text{Cu}_2\text{O}$  nanoparticles easily to  $\text{g-C}_3\text{N}_4$ . Meanwhile, the photoinduced holes on the  $\text{g-C}_3\text{N}_4$  surface can move to  $\text{Cu}_2\text{O}$  due to the 1.84 eV VBM energy level difference between the two components. Thus, the possibility for the electron-hole recombination could be greatly reduced by charge carrier transfer between  $\text{g-C}_3\text{N}_4$  and  $\text{Cu}_2\text{O}$  induced by proper Type II band alignment.

### 3.5. Photocatalytic performance for hydrogen production

The photocatalytic activity of  $\text{Cu(X wt\%)-g-C}_3\text{N}_4$  was evaluated by hydrogen production reaction under visible light ( $\lambda > 420 \text{ nm}$ ), as shown in Fig. 8. All the samples are photocatalytically active and stable for hydrogen production. No hydrogen was detected in the absence of either photocatalyst or light irradiation. The rate of hydrogen evolution over pure  $\text{g-C}_3\text{N}_4$  was  $141.6 \mu\text{mol/h/g}$ . With  $\text{Cu}_2\text{O}$  contents increasing, the photocatalytic activity was improved, with the highest activity obtained for  $X=0.05$ , and the hydrogen evolution rate achieved  $241.3 \mu\text{mol/h/g}$ . However, the photocatalytic activity was decreased with the further increasing of loading contents of  $\text{Cu}_2\text{O}$  for  $\text{Cu(X wt\%)-g-C}_3\text{N}_4$  ( $X=0.1-1.0$ ).

To clarify the photocatalytic hydrogen production reaction mechanism, we must make it clear that the  $\text{Cu}_2\text{O}$  NPs influenced the activity of  $\text{g-C}_3\text{N}_4$  via three effects: (1) efficient charge separation induced by the Type II band alignment; (2) acting as visible light sensitizers; (3) the negative shading effect [14,31]. The shading effect implied that more  $\text{Cu}(\text{NO}_3)_2$  addition will lead to the formation of much larger  $\text{Cu}_2\text{O}$  NPs covering on the surface of  $\text{g-C}_3\text{N}_4$  and then reduce the numbers of  $\text{g-C}_3\text{N}_4$  active sites available for  $\text{H}_2$  production. Note that effect (2) and (3) were both related to the  $\text{Cu}_2\text{O}$  content, that is, the larger the content, the stronger the effects of both (2) and (3). As shown from the UV-vis diffuse reflectance spectra in Fig. 5, the optical absorption of these photocatalysts were improved due to  $\text{Cu}_2\text{O}$  NPs modification, given the Type II band alignment, it was possible for the photoexcited electrons in  $\text{Cu}_2\text{O}$  NPs to transfer to  $\text{g-C}_3\text{N}_4$ , in other words, the  $\text{Cu}_2\text{O}$  NPs could act as visible light sensitizers. However, for  $\text{Cu(X wt\%)-g-C}_3\text{N}_4$  ( $X=0.02, 0.05$ ), the amounts of  $\text{Cu}_2\text{O}$  were too small to cause

**Fig. 9.** Schematic of band structure and charge transfer process in  $\text{Cu}_2\text{O}$  NPs/ $\text{g-C}_3\text{N}_4$  for photocatalytic hydrogen generation.

obvious light absorption improvement or obvious shading effect, then the photocatalytic activity improvement should be mainly due to the efficient charge separation induced by the Type II band alignment. For larger amounts of  $\text{Cu}_2\text{O}$  NPs loading ( $X=0.1\text{--}1.0$ ), although the light absorption ability was further improved, the negative shading effect turned much worse, which might greatly offset the effects of (1) and (2) and was detrimental for photocatalytic hydrogen production reaction.

Hydrogen production over mechanical mixture of  $\text{Cu}_2\text{O/g-C}_3\text{N}_4\text{-M}$  composite as reference was also tested. By comparison to  $\text{Cu}(0.05\text{ wt\%})\text{-g-C}_3\text{N}_4$ , the reference sample of  $\text{Cu}_2\text{O/g-C}_3\text{N}_4\text{-M}$  composite shows much lower photocatalytic activity under visible light, with hydrogen production rate to be only  $142.0\text{ }\mu\text{mol/h/g}$ . This result indicates that the one-pot in-situ reduction method favors the formation of  $\text{Cu}_2\text{O/g-C}_3\text{N}_4$  p–n heterojunction with intimate surface contact, and consequently resulting in efficient charge carrier separation between the two components, as illustrated in Fig. 9. The formation mechanism of the  $\text{Cu}_2\text{O}$  NPs on  $\text{g-C}_3\text{N}_4$  is still not very clear and needs further investigation, but it is preliminarily considered that the reduction of  $\text{Cu}^{2+}$  to  $\text{Cu}^+$  is relevant to the reducing  $\text{NH}_3$  atmosphere created by the deammonation process (Fig. S4), through which melamine is thermal-condensed to  $\text{g-C}_3\text{N}_4$  [8]. Besides, the well mixture of  $\text{Cu}^{2+}$  ions and melamine molecules in the precursor aqueous solution might favor the intimate contact between  $\text{Cu}_2\text{O}$  and  $\text{g-C}_3\text{N}_4$  and consequently the formation of p–n heterojunction.

It was reported that  $\text{Cu}_2\text{O}$  is not stable for photocatalytic reaction, due to the easy reduction and oxidation of  $\text{Cu}^+$  to  $\text{Cu}^0$  and  $\text{Cu}^{2+}$ , respectively [32]. In order to investigate the photocatalytic stability, the photocatalytic experiment was run for 5 cycles. As shown in Fig. S5 in Supplementary Information,  $\text{Cu}(0.05\text{ wt\%})\text{-g-C}_3\text{N}_4$  shows quite good stability for photocatalytic hydrogen production during the 35 h reaction, with hydrogen production rate kept at  $\sim 241.3\text{ }\mu\text{mol/h/g}$ . The almost unchanged Cu 2p XPS spectra of  $\text{Cu}(1.0\text{ wt\%})\text{-g-C}_3\text{N}_4$  after 5-cycle photocatalytic test (Fig. S6, Supplementary Information) further evidences the good stability of  $\text{Cu}(1.0\text{ wt\%})\text{-g-C}_3\text{N}_4$ , without changing the chemical states of  $\text{Cu}^+$ .

#### 4. Conclusions

$\text{Cu}_2\text{O}$  NPs modified  $\text{g-C}_3\text{N}_4$  photocatalysts with varied  $\text{Cu}_2\text{O}$  contents were successfully prepared via a one-pot in-situ

reduction method, which favored the formation of p–n heterojunction between  $\text{Cu}_2\text{O}$  and  $\text{g-C}_3\text{N}_4$ . As a result, the photocatalytic activity for hydrogen production over  $\text{g-C}_3\text{N}_4$  under visible light was greatly improved by  $\text{Cu}_2\text{O}$  NPs modification. The hydrogen evolution rate was improved from  $141.6\text{ }\mu\text{mol/h/g}$  (pure  $\text{g-C}_3\text{N}_4$ ) to  $241.3\text{ }\mu\text{mol/h/g}$  ( $\text{Cu}(0.05\text{ wt\%})\text{-g-C}_3\text{N}_4$ ) by photoactivity enhancement up to  $\sim 70\%$ . It was believed that the  $\text{Cu}_2\text{O}$  NPs could act as sensitizers for improved visible light absorption and the formed p–n heterojunction led to efficient charge separation induced by the Type II band alignment.
